# Overview

- **Introduction to imaging**
  - **Image Acquisition**
  - **Artifacts**
  - ◆ **Quality control**
- ◆ **Analyses**

# Medical images

- **The key distinguishing characteristic of medical images is that you get to look at the interior of objects**
  - ◆ **Instead of a 2D array of data (like photos)...**
  - ◆ **You get a full 3D volume of data: for each  $(x,y,z)$  location in space you have a measurement of some aspect of the material at  $(x,y,z)$**
  - ◆ **The images are referred to as volumetric images or tomographs**

# Medical image acquisition

- **Scientific principles that underlie MRI and PET:**
  - ◆ **If you shoot beams of electromagnetic energy into biological tissue, the amount of time it takes for the tissue to release that energy depends on the type of material**
  - ◆ **If you inject biological tissue with a radioactive substance, you can tell where the substance goes by detecting the radioactive decay**

# Magnetic Resonance Imaging

- **Basics:**
  - ◆ **If you excite atoms (beam energy into them) they gradually relax (let off the energy over time)**
  - ◆ **How quickly they let off the energy depends on the structure of the atom and the organization of the atoms surrounding them: so if you can record how quickly a set of atoms lets off the energy you beam into it, you can figure out what material the atoms are in**

# Magnetic Resonance Imaging

- Generally, they let varying amounts of energy off in all directions
- So if you beam energy into a bunch of atoms and set up detectors all around it to detect the energy being let off, the signal going into the detectors will be somewhat random

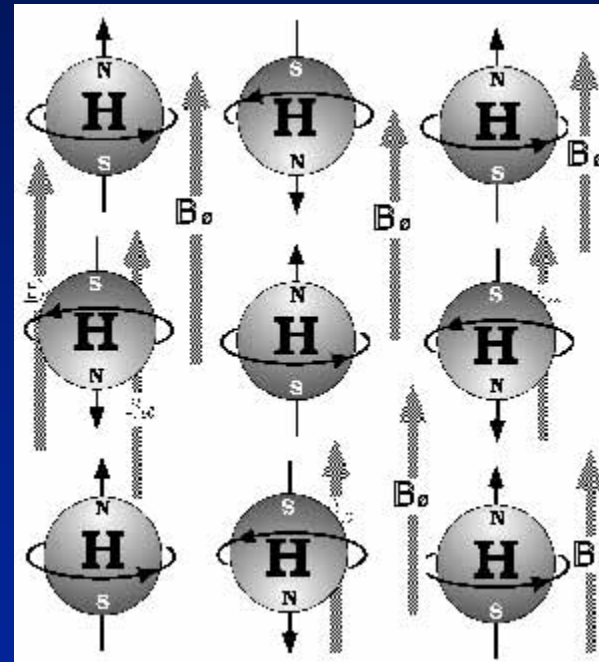

# Magnetic resonance imaging (MRI)

- However, some atoms have asymmetries: atoms like  $^1\text{H}$ ,  $^{31}\text{P}$ ,  $^{13}\text{C}$ ,  $^{19}\text{F}$  have a non-zero nuclear spin
- Valence electrons spin around the nucleus in a particular orbit and induce a tiny magnetic field along the atomic pole
- Normally, these poles are oriented at arbitrary orientations

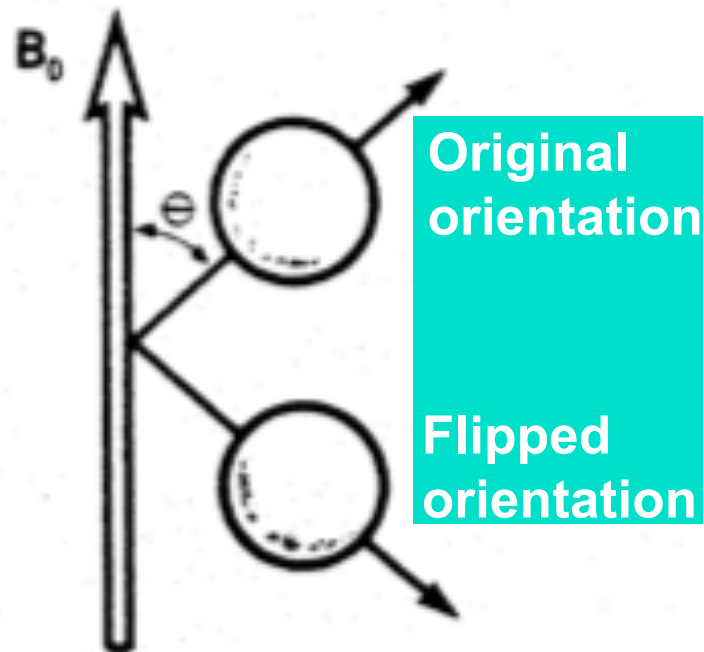

# Magnetic resonance imaging (MRI)

- But if you apply an external magnetic field ( $B_0$ ), the atomic poles tend to line up along the direction of that field. They spin at some angle with respect to the  $B_0$  direction; the stronger  $B_0$  is, the more they align with  $B_0$

# Magnetic resonance imaging (MRI)

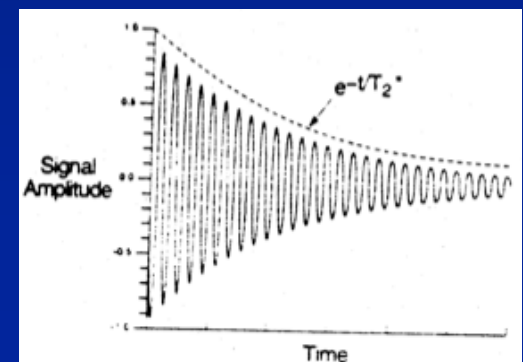

- The radio-frequency (RF) pulse
  - ◆ Perturbs the spin and
  - ◆ They gradually release their energy in predictable directions while reorienting themselves toward  $B_0$
- Energy is released orthogonal to  $B_0$
- By having a detector orthogonal to  $B_0$ , we can record how quickly the precessing atoms release their energy, and thus back out the material properties of the atoms

# T1 and T2

T1-exponential recovery of  $M_z$  in time  
T2-exponential decay of signal

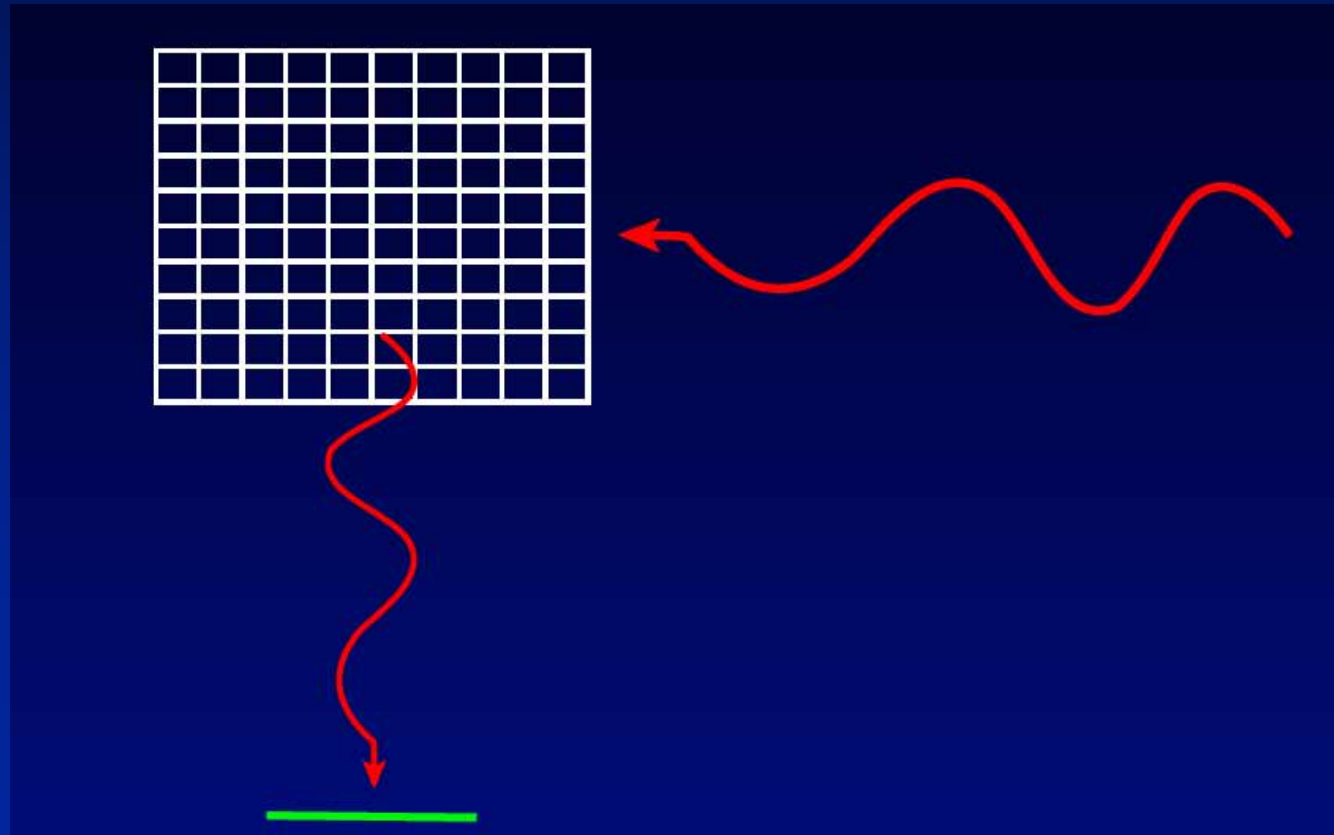

# Tissue Specific T1/T2

# Magnetic resonance imaging

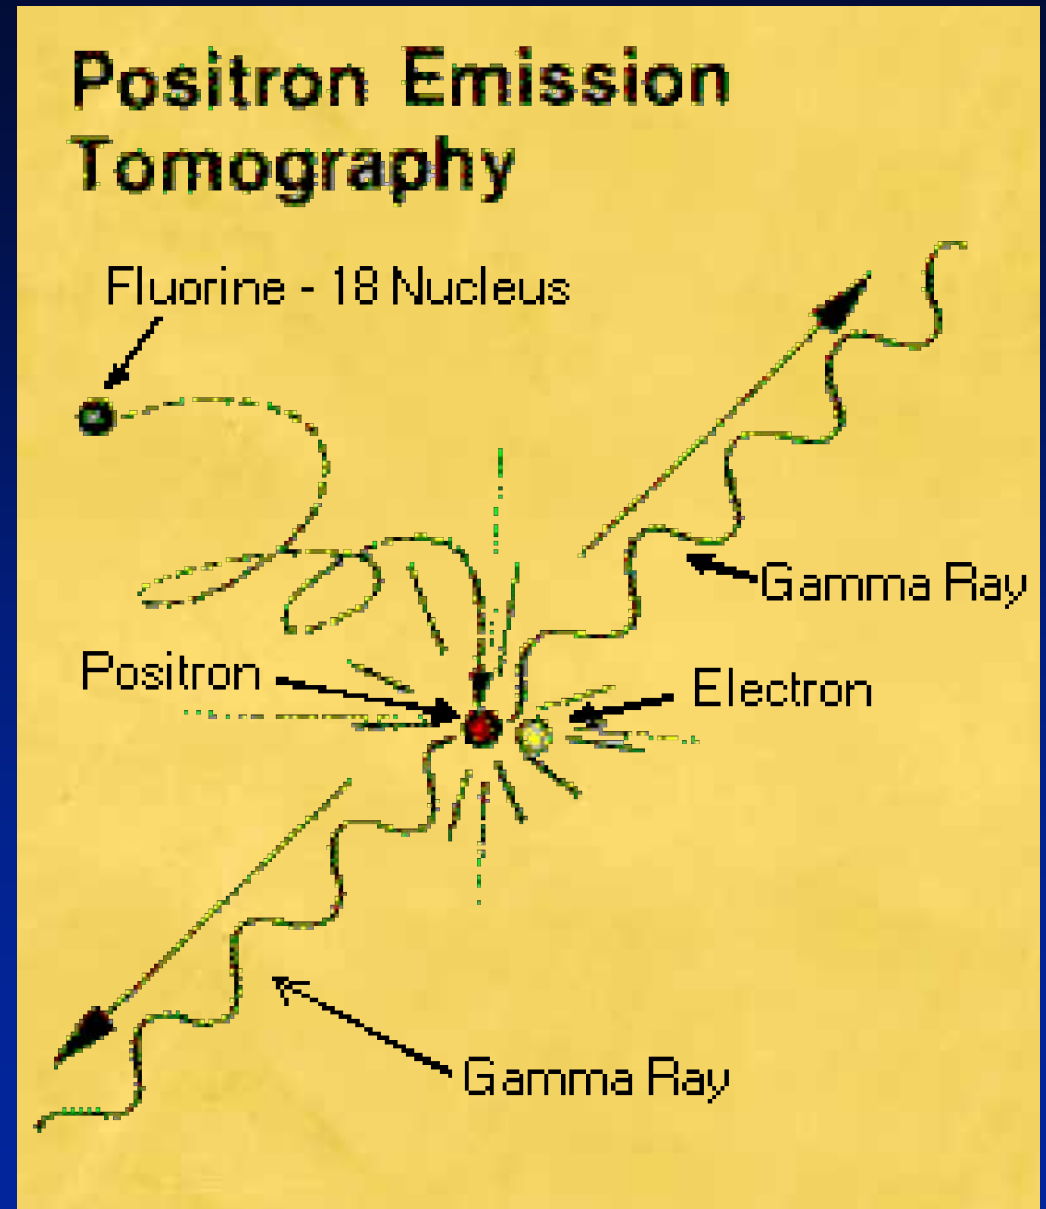

- A receiver picks up this emitted energy after the RF pulse is administered.
- Based on the time course of energy captured by the receiver, we back out material properties at each spatial location that is consistent with all the receiver data.

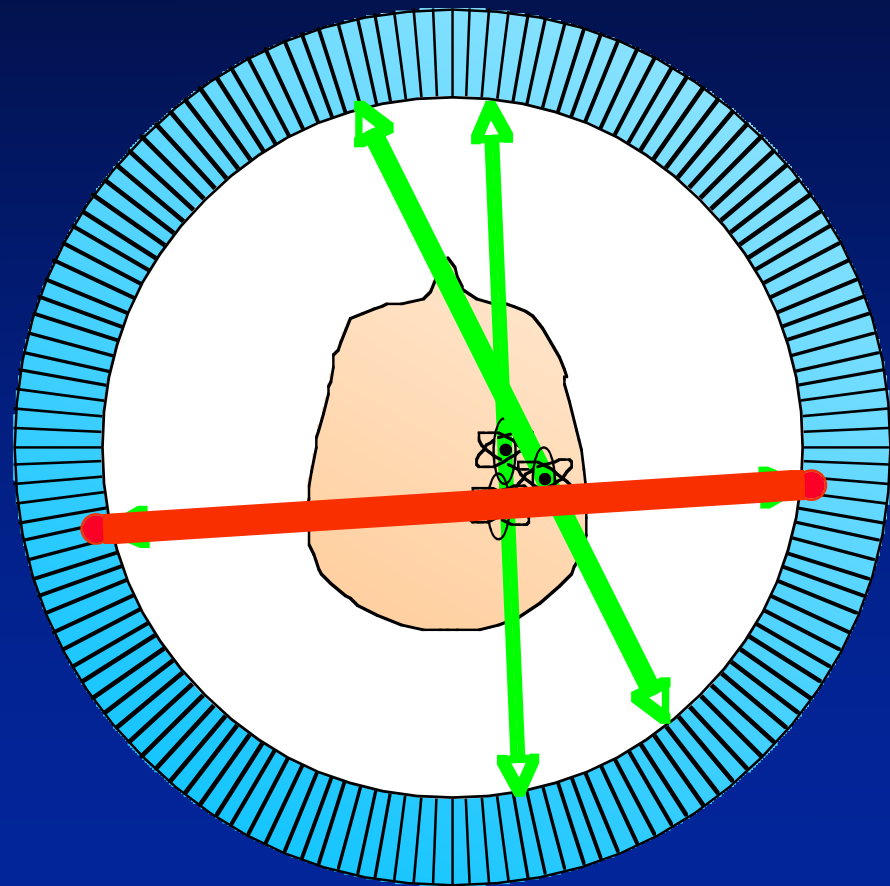

# Positron Emission Tomography

- Let's say you have a radioactive substance (a radioisotope) at some point in space
- "Radioactive" means it decays by emitting high-energy charged particles
- When it emits a positively-charged particle-- a positron-- it smashes into an electron, which annihilates both of them
- The by-product of this reaction is a pair of high-energy photons (gamma rays) that shoot off 180 degrees apart from each other

# Positron Emission Tomography

- If we can detect two emitted gamma rays that are 180 degrees apart from each other and hit the detectors at the same time, we know that a positron must have been emitted somewhere along the line between them: the **line of response**
- The radioisotope emits many, many positrons that cause gamma rays to shoot off in all directions
- Intersect all the lines of response to determine where in space the radioisotope is
- In this way the gamma rays act as a sort of “homing beacon” for the radioisotope

# Positron emission tomography

## ● Specific Uses

- ◆ Attach radioisotopes to molecules that are used in normal metabolism (e.g. F18)
  - Radiation is emitted during metabolism
- ◆ Attach radioisotopes to drugs acting at specific receptors
  - Radiation is emitted during interaction with receptor
- ◆ Attach radioisotopes to molecules that interact with specific protein conformations (e.g. PiB)
  - Radiation is emitted when molecule interacts with protein

# Key problem with PET

- Each radioisotope has a half-life: it only spits out positrons for a short period of time
- Fluorine has a half life of 2 hours
- Heavy oxygen is more like 20 minutes
- Meaning you better be VERY close to a cyclotron to use  $^{15}\text{O}$ .

# Summary

- **MRI examines how magnetic-field-aligned materials give off RF energy**
  - ◆ **High spatial resolution**
  - ◆ **High tissue contrast that can be varied**
- **PET attaches radioactive isotopes to molecules used in metabolism, receptors and even protein-protein interaction**

# Issues of Image Quality

# Signal to Noise of Various Systems

# Effect of SNR on Segmentation

# Artifacts

- Movement
- Foreign bodies
- Field Inhomogeneity
  - B0: Geometric Distortion
  - B1: Intensity inhomogeneity

# MR Artifacts: Motion

- MR image reconstruction methods assume the patient is sitting still. Here is an abdominal MR image taken while the subject is breathing
- Motion is a problem for all imaging modalities; they all assume the subject is sitting perfectly still

Raw image

Image after correction  
for motion

# MR Artifacts: Motion

- **Correct for respiratory motion by:**
  - ◆ **Telling the subject to hold his/her breath**
  - ◆ **Respiratory gating: Take repeated scans at the same point in the subject's respiratory cycle**
- **Increasing scanning speed**
  - ◆ **Taking many fast scans, aligning them, and averaging helps to average out the noise while compensating for motion**

# MR Artifacts: Metal

- Pieces of metal can distort the magnetic field and cause all sorts of problems

[wwwrad.pulmonary.ubc.ca/stpaulsstuff/MRartifacts.html](http://wwwrad.pulmonary.ubc.ca/stpaulsstuff/MRartifacts.html)

# MR Artifacts: Geometric Distortion

- We start out assuming that our magnet generates a magnetic field ( $B_0$ ) that is constant (same direction and magnitude) throughout the 3D space.

What it looks like without  
geometric distortion

What it looks like  
with geometric  
distortion

# MR Artifacts: Intensity distortion

- **Magnetic field irregularities in the gradient coil (B1) can also cause intensity distortions in parts of the image**

What the image looks like with intensity distortion

What it looks like without it

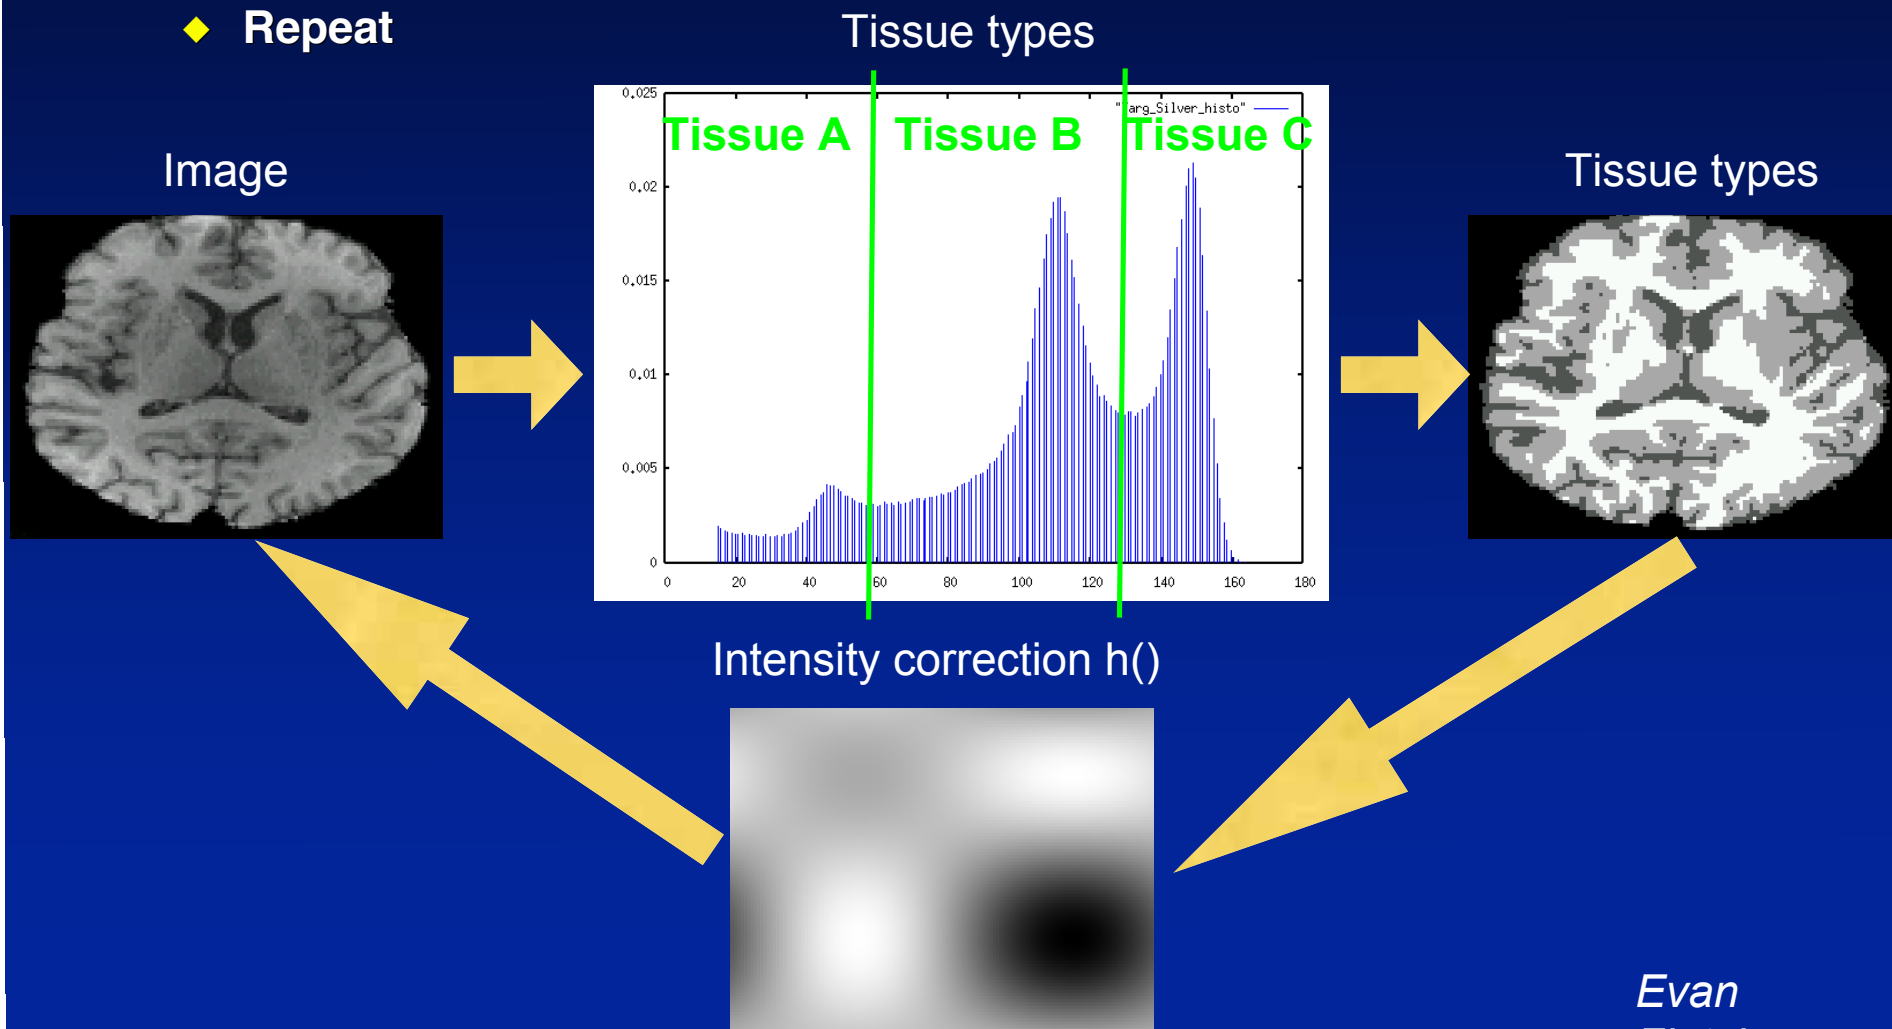

*E.F. Jackson*

# Correcting intensity distortion

- Assume that all voxels that belong to the same tissue type have the same intensity
- Assume  $h()$  is the function that defines image inhomogeneities
  - ◆ IF we know the tissue type of all voxels, we can estimate what  $h()$  is
    - All the voxels of type  $T$  should have the same intensity  $I_T$
    - If  $[x,y,z]$  is of tissue type  $T$ ,  $h([x,y,z])=I'([x,y,z])-I_T$
    - $h$  is usually assumed to be a smoothly-varying, low-dimensional function, so these initial guesses at  $h([x,y,z])$  can be fit to a parametric model

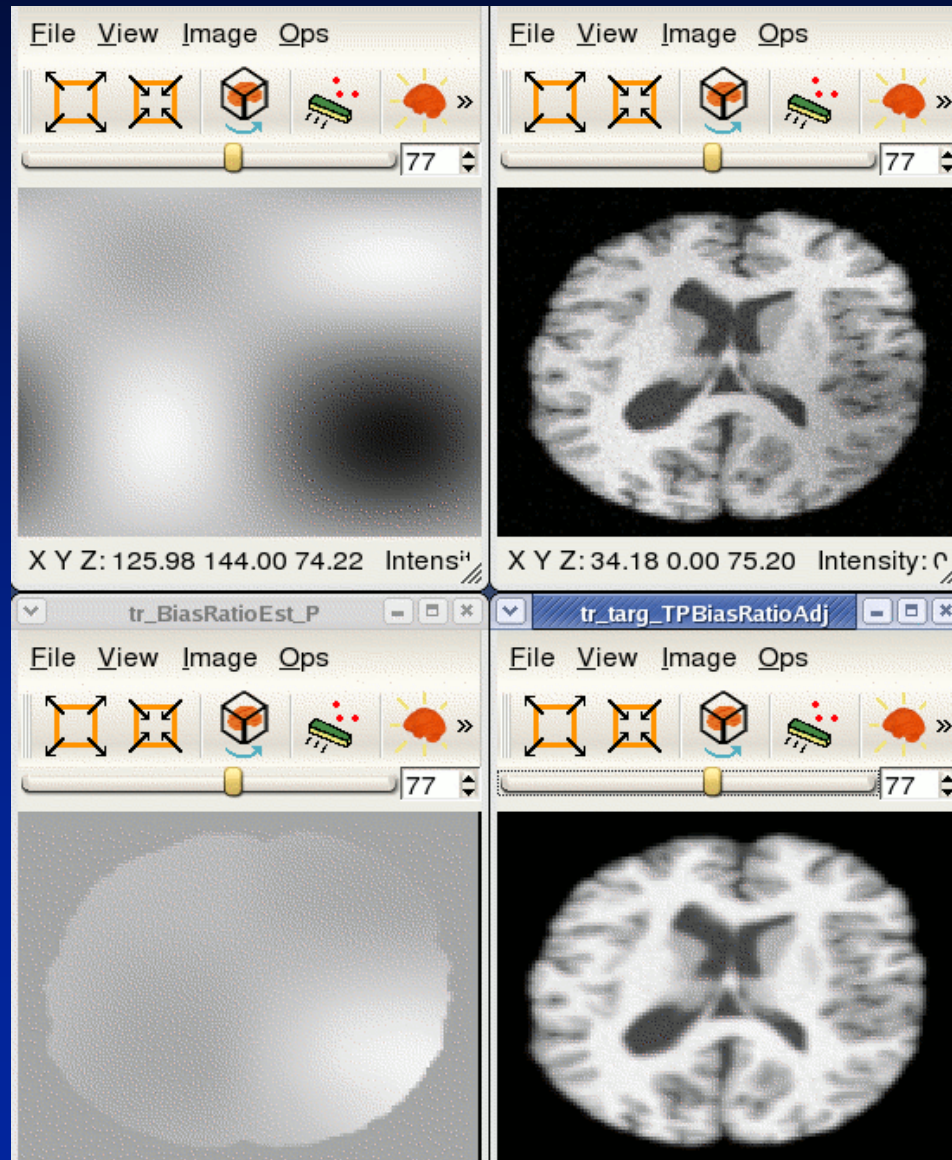

# Correcting intensity distortion

- One common solution:
  - ◆ Estimate the tissue types by simple thresholding of the image intensity
  - ◆ Use those tissue types to estimate  $h$
  - ◆ Update the image intensity based on the current  $h$
  - ◆ Repeat

# Correcting intensity distortions: examples

Intensity distortion:  $h()$

Distorted image

Corrected image

Intensity correction:  $-h()$

# Image Analysis

- Manual ROIs
- Segmentation
- Alignment
- SPM
- Free-Surfer

# Regions of Interest (ROI)

- **Manual**

- ◆ **Anatomically defined, usually by expert**
- ◆ **Detailed discussion of boundaries**
- ◆ **Documented procedure with high precision**

# Hippocampus

## Differences of anatomical landmarks among protocols after semantic harmonization.

### Plane of tracing

Axis of hippocampus  
[B,C,dTM,J,L,S,W] AC-PC line [H,K,M,Pa,Pr]

### Most posterior slice

Where inferior and superior colliculi are jointly visualized [B]

Where crus/crura of fornix/ces is/are visible in full profile  
[C,dTM,J,K,L,S,W]

Where gray matter is visible inferomedially to the trigone of the lateral ventricle  
[H,M,Pa,Pr]

### Superior border

Lower border of alveus/fimbria [B,H,K,Pa,S]

Upper border of alveus/fimbria  
[C,dTM,J,L,M,Pr,W]

### Separation subiculum/enthorinal cortex

vertical line from the CA to the WM of the parahippocampal gyrus [C]

Oblique line with same inclination of parahippocampal WM, connecting the inferior part of the subiculum to the quadrigeminal cistern  
[K,L,M,Pr,W]

Horizontal line from the highest medial point of the parahippocampal WM to the cistern [B,dTM,H]

Line outlining the contour of white matter of parahippocampal gyrus [J,Pa,S]

AC= anterior commissure; PC= posterior commissure; CA=cornu Ammonis; WM=white matter.

# Segmentation

- **Reliable determination of voxels associated with distinct tissue types**
  - ◆ Gray matter
  - ◆ White matter
  - ◆ CSF
  - ◆ +/- White matter hyperintensities

# Expectation Maximization

- Image consists of an array of  $y$  intensities
- Each voxel ( $y_i$ ) has a single intensity
- Segmented image is an array of labels  $x$  drawn from a small set of labels  $k$ .
- Given a conditional probability density,  $p$  we seek optimal labeling  $x^*$  such that:
  - ◆  $x^* = \arg \max_x p(x/y)$

# Bayesian Theory

- $x^* = \arg \max_x p(y/x) p(x)$
- Where  $p(y/x)$  is the measurement model (pixel intensity distribution)
- $p(x)$  = priors
  - ◆ Local
    - Markov-random fields

# Steps in Segmentation

Model to estimate initial tissue distributions  
Initial segmentation based on assignment  
Results of iterations

# Segmentation based on MRF Adaptation

# Assumptions

- **Voxel intensity (the most common type of image segmentation) reflects differences in tissue classes**
- **The underlying distribution of each tissue type has a known mean and standard deviation**
- **The distribution of intensities about the mean is assumed to be gaussian**

# WMH Detection from MRI

## Bayesian Inference Model

Use two key sources of information to determine whether there is a white matter hyperintensity at each voxel:

### Prior knowledge

Do WMHs tend to occur at this voxel in general?

### The image signal

Does it look like a WMH on PD, T1, and T2 MRI?

Combine these two sources of information in a **Bayesian inference framework**.

# Image Alignment

- **Fundamental to image processing**
  - ◆ **Places two images in common location**
    - **Target**
    - **To each other**
  - ◆ **Look at similar areas across multiple images**
  - ◆ **Look at differences in same individual over time**

# Principles of image alignment

- Given 2 images  $I_1$  and  $I_2$  as volumetric images  
 $I([x\ y\ z])$
- Estimate a geometric transformation of  $I_1$  that aligns it to  $I_2$ :  $g([x\ y\ z]) \rightarrow [x'\ y'\ z']$
- $g$  should align corresponding parts of the objects shown in  $I_1$  and  $I_2$  to each other:
  - ◆ If  $I_1$  and  $I_2$  are images of the same instance of the same object,  $I_1([x\ y])$  and  $I_2(g([x\ y]))$  should be pixels covering the same part of the same object
  - ◆ If  $I_1$  and  $I_2$  are images of the same *type of* object,  $I_1([x\ y])$  and  $I_2(g([x\ y]))$  should be pixels covering the same general part of the object shown

# Components of image registration

- **Transformation model:** The functional form of  $g()$ , which is parameterized by a vector of parameters  $\theta$ .
- **Metric:** A function  $M(I_1([x\ y\ z]), I_2(g([x\ y\ z])))$  that is low when  $g$  aligns  $I_1$  and  $I_2$  well and high when it does not
- **Interpolation scheme:** Given an image  $I_1$  where  $I_1([x\ y\ z])$  is only defined at integer  $[x\ y\ z]$ , the interpolation scheme assigns intensities to  $I_1$  at floating point  $[x\ y\ z]$
- **Optimizer:** Iteratively finds  $\theta$  that minimize  $M$ 
  - ◆ Initial conditions: **A starting guess at  $\theta$**
  - ◆ Stopping conditions: **Criterion for determining when to stop trying to find better values of  $\theta$**

## Interpolation example:

Our transformation gives us this alignment between  $I_1$  and  $I_2$ , and to measure goodness-of-fit we need to evaluate  $I_1$  (black dots) at the in-between-pixel positions (clear dots) where  $I_2$ 's pixels get transformed to

# Transformation models

- ◆ Rigid transformations rotate and translate  $I_1$  to align it with  $I_2$
- ◆ Similarity transformations add isotropically scaling to this (e.g.,  $a*x, b*y, c*z$ )
- ◆ Affine transformations add anisotropic scaling and shearing

Above assume a single transformation function applied to all voxels in the image

- ◆ **Deformable transformations**
  - Local transformation in voxel locations based on regional comparisons (e.g. control points) allowing for different shape

# Transformation models

$$g_{\phi}(x,y,z)=T * [x \ y \ z]$$

**Affine model:** T is a 4x4 matrix of constants  
12 parameters: 3 rotations, translations, scalings, and shears

Global transformation: each pixel is moved the same amount

No local expansions or contractions

$$g_{\phi}(x, y, z) = \sum_{p=0}^K \sum_{q=0}^K \sum_{r=0}^K [a_{pqr1}, a_{pqr2}, a_{pqr3}] \cdot x^p y^q z^r$$

**Polynomial model:** the a coefficients are the parameters  
The number of parameters depends on your choice of K:  
the degree of the highest polynomial in your model  
More polynomials means a higher degree of possible deformation

# Nonrigid transformations

- **Semi-deformable models** allow the image to deform in more constrained, smooth ways
- **Fully-deformable models** allow each pixel to move around arbitrarily, in an unconstrained way
- Because they constrain the deformation less, fully-deformable methods have the potential to more accurately align the images together, even when one is a highly deformed version of the other
- But higher degrees of deformation usually imply more parameters that need to be estimated and the possibility of non-biological transformations

Affine

Semi-deformable

Fully-deformable

# Transformation models

$$g_{\phi}(x, y, z) = [x, y, z] + \sum_{p=0}^K [a_{p1}, a_{p2}, a_{p3}] \cdot d_p(x, y, z)$$

## Discrete cosine transform model:

The coefficients ( $a_p$ ) are the parameters;  $d_p()$  is the  $p$ th DCT basis function

The number of parameters depends on the number of DCT basis functions you include

Higher-order DCT basis functions corresponds to higher-frequency sinusoids: therefore higher degrees of deformation

$$g_{\phi}(x, y, z) = [x, y, z] + [\delta x, \delta y, \delta z]$$

## Fully-deformable model:

Each voxel is translated by its own individual displacement vector  $[dx, dy, dz]$

The number of parameters is high-- 3 per pixel!

The degree of deformation is arbitrary

# The metric

- The relationship between intensities in  $I_1$  and intensities in  $I_2$  can be complex, even if they are images of the same object
  - ◆ Consider two images of the same face in different lighting: parts of the face that are bright in one image may look dark in another
  - ◆ Two MR images of the same brain may look entirely different if the scanner or scanning parameters differ
- Therefore we use geometric and intensity transformations to model the relationship between  $I_1$  and  $I_2$ :  $I_1([x \ y \ z]) = h(I_2(g([x \ y \ z])))$
- Different metrics make different assumptions about the relationship

2 MR scans of the same brain with different scan parameters

# Linear intensity transformations

- Let's say that instead of assuming the two images have identical intensities, you assume that there is a linear relationship between them:  $h(x) = m \cdot x + b$
- The intensity differences between the two images will be high even if they are aligned perfectly
- Two Common Approaches:
  - ◆ Try to rectify the images to remove  $m$  and  $b$ : for example, set the means and variances of the images to the same constant values:  $I_1 \rightarrow (I_1 - \text{mean}(I_1)) / \text{variance}(I_1)$ 
    - Not possible if Image A and Image B have different Tissue contrasts
  - ◆ Use a metric that rewards  $I_1([x \ y \ z])$  and  $I_2(g([x \ y \ z]))$  if there is a consistent linear relationship between intensities in  $I_1([x \ y \ z])$  and in  $I_2(g([x \ y \ z]))$

# Linear intensity transformations

- Normalized correlation rewards the two images for having a consistent linear relationship in intensities:

$$\frac{\sum_{x,y,z} I_1(x,y,z) * I_2(g(x,y,z))}{\sqrt{\sum_{x,y,z} I_1(x,y,z) * I_1(x,y,z) + \sum_{x,y,z} I_2(g(x,y,z)) * I_2(g(x,y,z))}}$$

$I_1([x y z])$

$I_2(g([x y z]))$

# Mutual information

- Mutual information is a way of rewarding images when they have an intensity relationship that is consistent in any way-- regardless of what that relationship is (linear, non-linear, etc.)
- Very simple requirement: If  $h()$  transforms intensity  $x$  to intensity  $y$  for **one** pixel, it should transform **all** pixels of intensity  $x$  to intensity  $y$
- In other words, the distribution of  $h(x)$ , given  $x$ , should be highly peaked around  $y$
- Note that this says nothing about the functional form of  $h()$ -- whether it is linear, quadratic, etc. Just that it should be consistent, transforming all of the  $x$  pixels to  $y$  no matter where they are in the image

$I_1([x \ y \ z])$

$I_2(g([x \ y \ z]))$

Ideal case for MI: A tightly-clustered joint histogram of  $I_1$  and  $I_2$

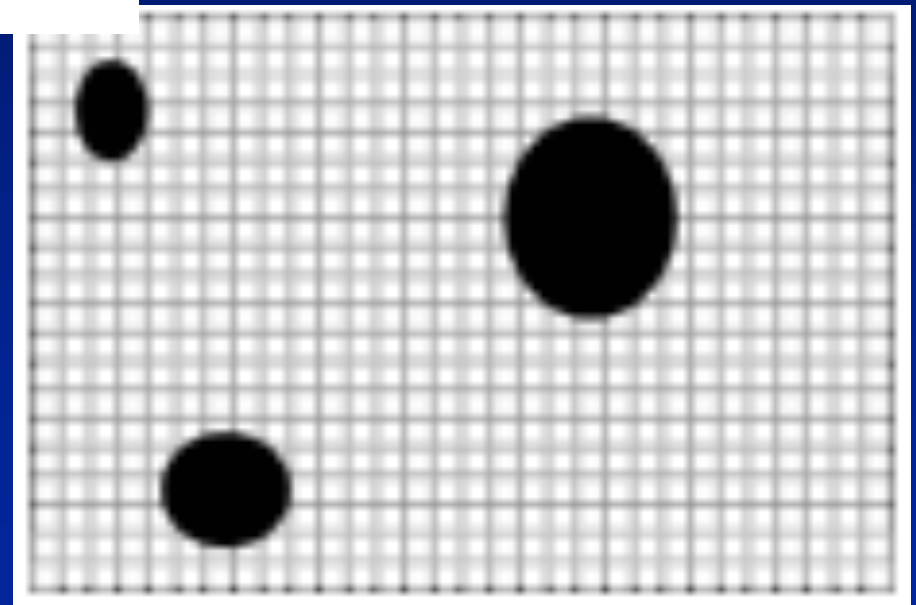

Each intensity level in  $I_1$  gets mapped to a small number of intensities in  $I_2$

# Mutual information

- The idea that  $h$  should be as one-to-one as possible is formalized by looking at the joint distribution of  $I_1$  and  $I_2$  intensities --  $P_{AB}(a,b)$  -- and the marginal distributions of intensities in  $I_1$  and  $I_2$ :  $P_A(a)$  and  $P_B(b)$
- The entropy of these distributions is  $H(A,B)$ ,  $H(A)$ , and  $H(B)$

$$I(A, B) = \sum_a \sum_b P_{AB}(a, b) \log \frac{P_{AB}(a, b)}{P_A(a)P_B(b)}$$

$I_1([x \ y \ z])$   
intensities

$I_2(g([x \ y \ z]))$  intensities

# Examples

1.5 T

3.0 T

# Number of MRI Acquisitions

Everyone received 1.5 T MRI and 50% received an additional 3T for comparison

# Analysis Groups

- UCSF—Norbert Schuff
  - ◆ SNT hippocampus
  - ◆ Freesurfer
- UCLA—Paul Thompson
  - ◆ Tensor morphometry
- UCD—DeCarli/Carmichael
  - ◆ White matter disease/infarcts
- UCSD—Anders Dale
  - ◆ Modified Freesurfer
- University College of London—Nick Fox
  - ◆ BBSI

# Summary Results

# Measures of Change in MCI: ADAScog13 vs Hippocampal Volume

ADNI, unpublished data.

# Mean $\pm$ (SD) of ADNI Variables

Variable name	Annualized mean change by diagnosis		
	NC	MCI	AD
CSF A $\beta$ <sub>42</sub>	-0.94 (18)	-1.4 (17)	-0.1 (14)
CSF Tau	3.45 (13)	2.34 (21)	1.24 (24)
PIB	0.098 (0.18)	-0.008 (0.18)	-0.004 (0.25)
FDG-PET: SumZ2PNS	-177 (1532)	752 (2950)	2993 (4040)
FDG-PET: ROI-avg	-0.006 (0.06)	-0.015 (0.064)	-0.055 (0.067)
FDG-PET: DD-fROI	-0.019 (0.037)	-0.047 (0.030)	-0.081 (0.047)
Hippocampus	-40 (84)	-80 (91)	-116 (93)
Ventricles	848 (973)	1551 (1520)	2540 (1861)
ADAS-cog total	-0.54 (3.05)	1.05 (4.40)	4.37 (6.60)
MMSE	0.0095 (1.14)	-0.64 (2.5)	-2.4 (4.1)
CDR-SB	0.07 (0.33)	0.63 (1.16)	1.62 (2.20)
RAVLT 5-trial total	0.29 (7.8)	-1.37 (6.6)	-3.62 (5.6)

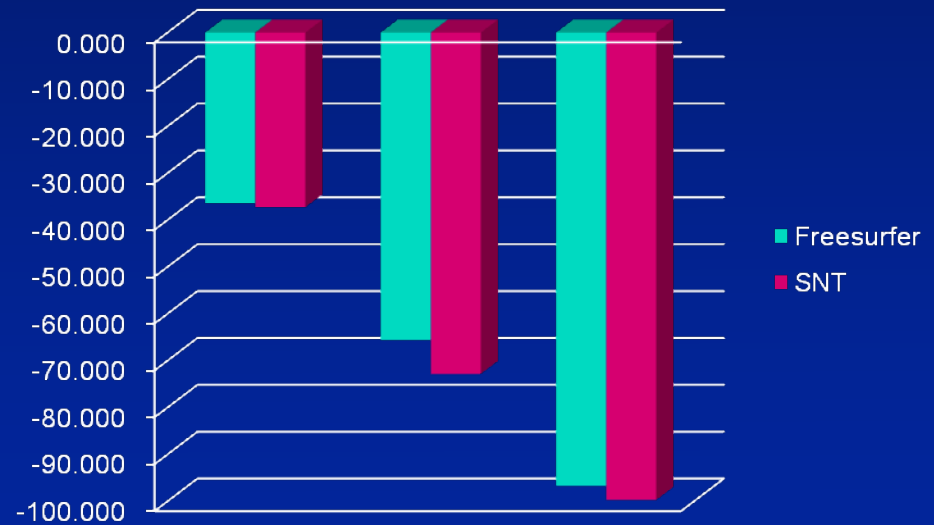

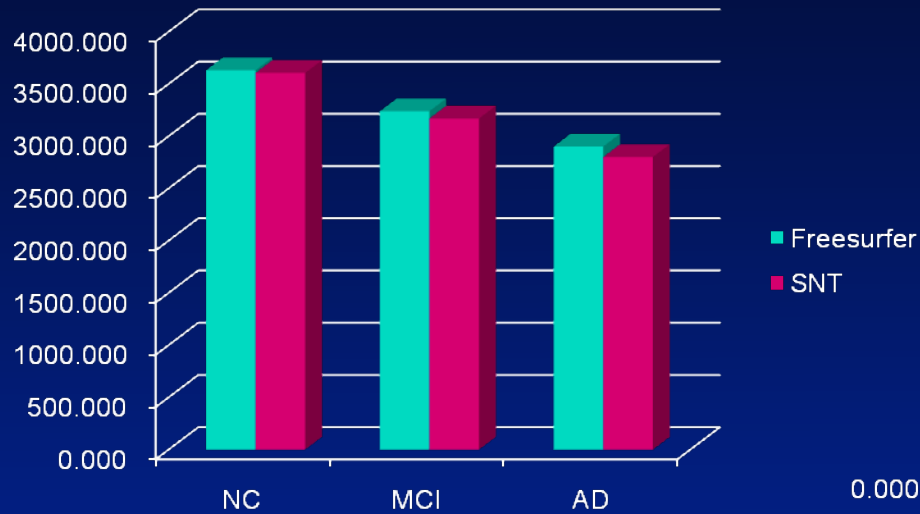

# Baseline MRI Measures
